

Addition spectra of quantum dots: the role of dielectric mismatch

Alberto Franceschetti, Andrew Williamson and Alex Zunger
National Renewable Energy Laboratory, Golden, CO 80401

Abstract

Using atomistic pseudopotential wave functions we calculate the electron and hole charging energies of InAs quantum dots. We find that the charging energies depend strongly on the dielectric constant ϵ_{out} of the surrounding material, and that when the latter is smaller than the dielectric constant of the dot (weak external screening) the electron-electron and hole-hole interactions are dominated by surface polarization effects. We predict the addition energies and the quasi-particle gap as a function of size and ϵ_{out} . We find excellent agreement with recent single-dot tunneling spectroscopy data for $\epsilon_{\text{out}} = 6$.

Semiconductor quantum dots can be made with various dielectric coatings: Organic molecules [1,2], other semiconductors (e.g. self-assembled dots [3], core-shell nanocrystals [4], lithographically-etched dots [5], strain-induced dots [6]), or glasses [7]. It has been realized [8,9] that the dielectric environment can profoundly affect the optical and transport properties of quantum dots. This can be seen by considering the two processes described in Fig. 1, where a quantum dot of dielectric constant ϵ_{in} is embedded in a material of dielectric constant ϵ_{out} . Figure 1(a) depicts the process of adding three electrons to an otherwise neutral quantum dot. The initial configuration of the system, of energy E_0 , consists of a neutral dot in the ground state and a Fermi reservoir at the reference energy $\epsilon_{\text{ref}} = 0$. The “charging energy” μ_1 required to load the first electron into the quantum dot is

$$\mu_1 \equiv E_1 - E_0 = \epsilon_{e1} + \Sigma_{e1}^{\text{pol}}, \quad (1)$$

where E_1 is the total energy of the dot with one additional electron, ϵ_{e1} is the energy of the single-particle level $e1$ with respect to the reference energy ϵ_{ref} , and Σ_{e1}^{pol} is the self-energy of the additional electron interacting with its own image charge created by the dielectric mismatch at the surface of the dot [9]. The charging energy μ_2 to add the second electron to the quantum dot is

$$\mu_2 \equiv E_2 - E_1 = \epsilon_{e1} + \Sigma_{e1}^{\text{pol}} + J_{e1,e1}, \quad (2)$$

where $J_{e1,e1}$ is the Coulomb interaction between the two electrons. It includes a direct electron-electron contribution $J_{e1,e1}^{\text{Coul}}$ and a polarization contribution $J_{e1,e1}^{\text{pol}}$ arising from the interaction of one electron with the image charge of the other electron [9]. Finally, the charging energy for the third electron is

$$\mu_3 \equiv E_3 - E_2 = \epsilon_{e2} + \Sigma_{e2}^{\text{pol}} + 2J_{e1,e2} - K_{e1,e2}, \quad (3)$$

where $K_{e1,e2}$ is the exchange energy between two electrons with parallel spins in the $e1$ and $e2$ single-particle levels. The “addition energies” for the second and the third electrons are, respectively

$$\Delta_{1,2} \equiv \mu_2 - \mu_1 = J_{e1,e1}, \quad (4)$$

$$\Delta_{2,3} \equiv \mu_3 - \mu_2 = (\epsilon_{e2} - \epsilon_{e1}) + (\Sigma_{e2}^{\text{pol}} - \Sigma_{e1}^{\text{pol}}) + (2J_{e1,e2} - J_{e1,e1}) - K_{e1,e2}. \quad (5)$$

Since Σ_i^{pol} and $J_{i,j}^{\text{pol}}$ depend strongly on the dielectric constant of the surrounding material, the charging spectroscopy [5,10] of a quantum dot depends on its dielectric environment.

Figure 1(b) describes the process of removing an electron from the highest occupied orbital of a neutral quantum dot and placing it into the lowest unoccupied orbital of an identical dot (located at infinite distance from the first dot). The energy required by this process (“quasi-particle gap”) is the difference between the ionization potential and the electron affinity of the dot. The initial configuration, consisting of the two neutral dots in the ground state, has energy $2E_0$, while the final configuration has energy $E_1 + E_{-1}$, where E_{-1} is the energy of the quantum dot with a hole in the highest occupied orbital $h1$. The quasi-particle gap is then

$$\varepsilon_{\text{gap}}^{\text{qp}} = E_1 + E_{-1} - 2 E_0 = (\varepsilon_{e1} - \varepsilon_{h1}) + \Sigma_{e1}^{\text{pol}} + \Sigma_{h1}^{\text{pol}}, \quad (6)$$

where $\varepsilon_{\text{gap}} \equiv \varepsilon_{e1} - \varepsilon_{h1}$ is the single-particle (HOMO-LUMO) gap. We see that the quasi-particle gap depends, via the polarization self-energies Σ_{e1}^{pol} and Σ_{h1}^{pol} , on the dielectric environment. The optical gap differs from the quasi-particle gap by the electron-hole interaction $J_{h1,e1}$:

$$\varepsilon_{\text{gap}}^{\text{opt}} = \varepsilon_{\text{gap}}^{\text{qp}} - (J_{h1,e1}^{\text{Coul}} + J_{h1,e1}^{\text{pol}}). \quad (7)$$

Very recently single-dot tunneling spectroscopy was applied to InAs nanocrystals [10], measuring $\Delta_{N,N+1}$ and $\varepsilon_{\text{gap}}^{\text{qp}}$.

The effects of dielectric confinement on the excitonic gap and the charging energies of quantum dots have been addressed in the past [9,11–15] using the effective-mass approximation (EMA). Recent pseudopotential calculations [16] have demonstrated the importance of using an atomistic description of the quantum dot electronic structure for calculating the electron-hole Coulomb energy. The pseudopotential approach provides an accurate description of the wave function decay outside the quantum dot and of the interband coupling due to quantum confinement, which are critical for a correct evaluation of the polarization and Coulomb energies in small nanocrystals.

Using pseudopotential wave functions, we discuss here the effects of dielectric mismatch ($\epsilon_{\text{out}} \neq \epsilon_{\text{in}}$) on (a) the electron and hole charging energies $\mu_N = E_N - E_{N-1}$, where E_N is the ground-state energy of N electrons (or holes) in the quantum dot, (b) the addition energies $\Delta_{N,N+1} = \mu_{N+1} - \mu_N$, and (c) the quasi-particle band gap $\varepsilon_{\text{gap}}^{\text{qp}}$. We find excellent agreement with recent experimental results [10], and interpret the data in terms of Coulomb and polarization contributions [Eqs. (1) - (6)]. We show that depending on the ratio between ϵ_{in} and ϵ_{out} one encounters two physically distinct regimes of transport behavior:

(i) When $\epsilon_{\text{out}} \ll \epsilon_{\text{in}}$ (weak external screening) the electron-electron interaction $J_{i,j}$ is dominated by the polarization contribution $J_{i,j}^{\text{pol}}$, which depends only weakly on the single-particle states i and j . The charging energies μ_N depend strongly on the dielectric constant ϵ_{out} , and are widely spaced for various N (large addition energies $\Delta_{N,N+1}$).

(ii) When $\epsilon_{\text{out}} \geq \epsilon_{\text{in}}$ (strong external screening) the dominant contribution to $J_{i,j}$ is the Coulomb energy $J_{i,j}^{\text{Coul}}$, which is quite sensitive to the identity of the states i and j . The charging energies μ_N depend weakly on ϵ_{out} and are more closely spaced (small addition energies).

The practical significance of these results stems from the fact that, due to the long-range character of the Coulomb interaction and the exponential decay of the wave functions outside the quantum dot, dielectric confinement and quantum confinement can be physically separated. In fact, by changing the dielectric environment *far away* from the dot, while keeping the same barrier material next to the dot, one can control and tailor the electronic properties (such as $\Delta_{N,N+1}$ and $\varepsilon_{\text{gap}}^{\text{qp}}$) without affecting quantum confinement (i.e. the single-particle energies and wave functions).

We approximate the many-particle wave function Ψ_N of a system of N electrons in the conduction band of a quantum dot by a single Slater determinant constructed from the wave functions $\{\psi_i, i = 1 \cdots N\}$ of the N single-particle states occupied by the N electrons. The corresponding total energy is

$$E_N = E_0 + \sum_i (\varepsilon_i + \Sigma_i^{\text{pol}}) n_i + \sum_{i < j} (J_{i,j} - K_{i,j}) n_i n_j, \quad (8)$$

where ε_i are the conduction-band single-particle energy levels, Σ_i^{pol} are the polarization self-energies, $J_{i,j}$, $K_{i,j}$ are the electron-electron Coulomb and exchange energies, respectively, and n_i are the occupation numbers ($\sum_i n_i = N$). The ground state Ψ_N^0 corresponds to the configuration that minimizes the total energy E_N . In Eq. (8) we neglect: (i) the coupling between different Slater determinants (i.e. configuration-interaction effects), and (ii) the response of the single-particle wave functions ψ_i to the electrostatic field (i.e. self-consistent effects). These assumptions are sufficiently accurate in small, three-dimensional structures in the strong-confinement regime [16–18].

The single-particle energies ε_i and wave functions $\psi_i(\mathbf{r}, \sigma)$ are obtained here from the solution of the Schroedinger equation:

$$[-\nabla^2 + V_{\text{ps}}(\mathbf{r})] \psi_i(\mathbf{r}, \sigma) = \varepsilon_i \psi_i(\mathbf{r}, \sigma). \quad (9)$$

The pseudopotential of the quantum dot $V_{\text{ps}}(\mathbf{r})$ is obtained from the superposition of screened atomic potentials, which are fitted [19] to reproduce the bulk experimental optical transition energies and effective masses, as well as the surface work function. Spin-orbit coupling is fully included in the solution of the Schroedinger equation.

The interelectronic energies $J_{i,j}$ are given by:

$$J_{i,j} = e \sum_{\sigma} \int |\psi_i(\mathbf{r}, \sigma)|^2 \Phi_j(\mathbf{r}) d\mathbf{r}, \quad (10)$$

where $\Phi_j(\mathbf{r})$ is the electrostatic potential energy due to a charge distribution $\rho_j(\mathbf{r}) = e \sum_{\sigma} |\psi_j(\mathbf{r}, \sigma)|^2$ in a dielectrically inhomogeneous medium. $\Phi_j(\mathbf{r})$ satisfies the Poisson equation:

$$\nabla \cdot \epsilon(\mathbf{r}) \nabla \Phi_j(\mathbf{r}) = -4\pi e \rho_j(\mathbf{r}), \quad (11)$$

where $\epsilon(\mathbf{r})$ is the (position-dependent) macroscopic dielectric constant of the system. The Poisson equation is solved on a real-space grid using a finite-difference discretization of the gradient operator. The boundary conditions are obtained from a multipole expansion of the electrostatic potential [16]. The dielectric constant $\epsilon(\mathbf{r})$ changes smoothly from ϵ_{in} to ϵ_{out} , with a transition region of the order of the interatomic bond-length. The interelectronic energy $J_{i,j}$ can be separated into two contributions: (a) the direct Coulomb energy $J_{i,j}^{\text{Coul}}$, which corresponds to the interaction between two electrons in the quantum dot as if the dielectric constant was uniform throughout the system, and identical to the macroscopic dielectric constant of the quantum dot; and (b) the polarization energy $J_{i,j}^{\text{pol}}$ which accounts for the effects of the dielectric discontinuity at the interface between the quantum dot and the surrounding material, and the ensuing surface polarization charge.

The polarization self-energies Σ_i^{pol} are given by:

$$\Sigma_i^{\text{pol}} = \frac{e}{2} \sum_{\sigma} \int \psi_i^*(\mathbf{r}, \sigma) \Sigma(\mathbf{r}) \psi_i(\mathbf{r}, \sigma) d\mathbf{r}, \quad (12)$$

$$\Sigma(\mathbf{r}) = \lim_{\mathbf{r}' \rightarrow \mathbf{r}} [G(\mathbf{r}, \mathbf{r}') - G_{\text{bulk}}(\mathbf{r}, \mathbf{r}')], \quad (13)$$

where $G(\mathbf{r}, \mathbf{r}')$ is the Green's function associated with the Poisson equation [Eq. (11)], and $G_{\text{bulk}}(\mathbf{r}, \mathbf{r}')$ is the bulk Green's function. Here we use the analytical expression of $\Sigma(\mathbf{r})$ for a spherical quantum dot [12] of dielectric constant ϵ_{in} embedded in a medium of dielectric constant ϵ_{out} . The singularity of $\Sigma(\mathbf{r})$ at the surface of the dot is removed by applying a smoothing function $1 - e^{-(r-R)^2/\sigma^2}$, where σ is a broadening factor of the order of the bond length.

We consider InAs spherical nanocrystals of diameter $D = 30.3$ and 42.2 Å. The surface dangling bonds are passivated using a large-gap barrier material [19]. Our analysis of the envelope functions extracted for the pseudopotential wave functions shows that the first electron level ($e1$) is predominantly s -like, while the next 3 electron levels ($e2$, $e3$, and $e4$) are predominantly p -like. The first two hole levels ($h1$ and $h2$) have an s -like envelope function, while the next two hole levels ($h3$ and $h4$) have a p -like envelope function. Each single-particle energy level is doubly degenerate (because of time-reversal symmetry).

The self-energies Σ_i^{pol} , the polarization energies $J_{i,j}^{\text{pol}}$, and the Coulomb energies $J_{i,j}^{\text{Coul}}$ of the 30.3 Å diameter InAs nanocrystal are shown in Fig. 2 as a function of the external dielectric constant ϵ_{out} , for a few single-particle states i and j . We see that (i) both Σ_i^{pol} and $J_{i,j}^{\text{pol}}$ depend strongly on ϵ_{out} , and vanish when $\epsilon_{\text{out}} = \epsilon_{\text{in}}$ (vertical arrows in Fig. 2). (ii) When $\epsilon_{\text{out}} > \epsilon_{\text{in}}$ the polarization energies $J_{i,j}^{\text{pol}}$ become negative, thus acting to diminish the electron-electron interaction. (iii) The dependence of Σ_i^{pol} and $J_{i,j}^{\text{pol}}$ on the identity of the orbitals i and j (e.g. s or p) is rather weak, as shown in the insets in Fig. 2. (iv) There is a critical value of ϵ_{out} ($\epsilon_{\text{critical}} \sim 4$) such that for $\epsilon_{\text{out}} < \epsilon_{\text{critical}}$ the polarization energies $J_{i,j}^{\text{pol}}$ dominate over the Coulomb energies $J_{i,j}^{\text{Coul}}$.

The charging energies $\mu_N = E_N - E_{N-1}$, calculated from the total energies E_N given by Eq. (8), are shown in the central panel of Fig. 3 as a function of ϵ_{out} . The vertical arrow at the bottom of the figure denotes the value $\epsilon_{\text{out}} = \epsilon_{\text{in}}$, which divides the behavior into two domains: (i) In the weak screening regime ($\epsilon_{\text{out}} \ll \epsilon_{\text{in}}$) the charging energies are widely spaced, and their value depend strongly on ϵ_{out} . (ii) In the strong screening regime, on the other hand, the charging energies are closely spaced, and do not depend significantly on ϵ_{out} . The calculated charging spectrum is shown in Fig. 3 for $\epsilon_{\text{out}} = 1$ (left-hand side) and $\epsilon_{\text{out}} = 20$ (right-hand side), illustrating these two limiting behaviors.

The electron and hole addition energies $\Delta_{N,N+1}$ (spacings between peaks in the charging spectra of Fig. 3) are given in Table I for a few values of ϵ_{out} . We see that (i) for a given value of ϵ_{out} , the addition energy for the third electron $\Delta_{2,3}^{(e)}$ is significantly larger than the addition energy for the second electron $\Delta_{1,2}^{(e)}$. This can be explained by noting from Eqs. (4) and (5) that while $\Delta_{1,2}^{(e)}$ measures only the interelectronic repulsion, $\Delta_{2,3}^{(e)}$ includes also the single-particle gap between the s -like state $e1$ and the p -like states $e2$, $e3$, and $e4$ ($\epsilon_{e2} - \epsilon_{e1} = 0.40$ eV for the $D = 30.3$ Å nanocrystal and 0.36 eV for the $D = 42.2$ Å nanocrystal). (ii) The addition energies of the remaining electrons (up to $N = 8$) are approximately constant. The addition energy of the 9-th electron $\Delta_{8,9}^{(e)}$ is slightly larger, and reflects the single-particle gap between the p -like shell and the next shell. (iii) While Coulomb blockade effects were often interpreted in terms of the “constant interaction” model, whereby the addition energies $\Delta_{N,N+1}$ are constant and independent of N , we see that in small nanocrystals deviations from this model are noticeable, and are due primarily to the existence of single-particle gaps comparable or larger than the interelectronic energies $J_{i,j}$. These deviations are magnified

when polarization effects are small ($\epsilon_{\text{out}} \geq \epsilon_{\text{in}}$). (iv) The electron and hole addition energies become smaller as the size D increases and/or the dielectric constant ϵ_{out} decreases. (v) The quasi-particle gap $\epsilon_{\text{gap}}^{\text{qp}}$ depends strongly on ϵ_{out} , while the optical gap $\epsilon_{\text{gap}}^{\text{opt}}$ does not. This is so because in the optical gap $\Sigma_{h1}^{\text{pol}} + \Sigma_{e1}^{\text{pol}}$ and $J_{h1,e1}^{\text{pol}}$ tend to cancel [see Eq. (7)], so $\epsilon_{\text{gap}}^{\text{opt}} \sim (\epsilon_{e1} - \epsilon_{h1}) - J_{h1,e1}^{\text{Coul}}$. (vi) The optical gap is smaller than the quasi-particle gap. For $\epsilon_{\text{out}} \sim \epsilon_{\text{in}}$ the difference is $J_{h1,e1}^{\text{Coul}}$.

Figure 3 and Table I provide clear predictions of the charging energies and addition energies of InAs quantum dots. To compare with the experimental measurements of Banin *et al.* (Ref. [10]), in which ϵ_{out} is an unknown quantity, we first fit our calculated $\Delta_{1,2}^{(e)}$ for the smaller dot with the experimental value $\Delta_{1,2}^{(e)} = 0.22$ eV, finding that $\epsilon_{\text{out}} = 6$ gives a good fit (Table I). Using this value of ϵ_{out} , we then predict for $D = 30.3$ Å (experimental data in parenthesis for $D = 34$ Å) $\epsilon_{\text{gap}}^{\text{qp}} = 1.78$ (1.75), $\Delta_{1,2}^{(h)} = 0.24$ (0.20), $\Delta_{2,3}^{(h)} = 0.23$ (0.22), $\Delta_{2,3}^{(e)} = 0.64$ (0.71), and $\Delta_{3,4}^{(e)} = 0.24$ (0.23). Using the same value of ϵ_{out} , our predictions for $D = 42.2$ Å (experimental data in parenthesis for $D = 44$ Å) are: $\epsilon_{\text{gap}}^{\text{qp}} = 1.38$ (1.38), $\Delta_{1,2}^{(h)} = 0.16$ (0.20), $\Delta_{2,3}^{(h)} = 0.16$ (0.17), $\Delta_{1,2}^{(e)} = 0.15$ (0.14), $\Delta_{2,3}^{(e)} = 0.51$ (0.52), and $\Delta_{3,4}^{(e)} = 0.14$ (0.14). We see that we have excellent agreement with experiment. Our theory can be further used to decompose the experimentally measured quantities into distinct physical contributions. For example, for $D = 30.3$ Å the quasi-particle gap $\epsilon_{\text{gap}}^{\text{qp}} = 1.78$ eV includes [Eq. (6)] the single-particle gap $\epsilon_{e1} - \epsilon_{h1} = 1.71$ eV and the self-energy contribution $\Sigma_{h1}^{\text{pol}} + \Sigma_{e1}^{\text{pol}} = 0.07$ eV. The addition energy for the third electron $\Delta_{2,3}^{(e)} = 0.64$ eV includes [Eq. (5)] the single-particle contribution $\epsilon_{e2} - \epsilon_{e1} = 0.40$ eV, the Coulomb contribution $2J_{e1,e2}^{\text{Coul}} - J_{e1,e1}^{\text{Coul}} = 0.17$ eV, the polarization contribution $2J_{e1,e2}^{\text{pol}} - J_{e1,e1}^{\text{pol}} = 0.07$ eV, and a negligible self-energy contribution $\Sigma_{e2}^{\text{pol}} - \Sigma_{e1}^{\text{pol}}$. The exchange contribution $K_{e1,e2}$ is smaller than 0.02 eV, and can be neglected.

In conclusion, we predict the effects of the dielectric environment on the electron and hole charging energies and on the addition spectrum of semiconductor quantum dots. We find that the charging energies and the addition energies depend sensitively on the dielectric constant ϵ_{out} of the surrounding material via the self-energies Σ_i^{pol} and the polarization energies $J_{i,j}^{\text{pol}}$. When $\epsilon_{\text{out}} \ll \epsilon_{\text{in}}$ the charging energies are widely spaced in energy, and depend strongly on ϵ_{out} . When $\epsilon_{\text{out}} \geq \epsilon_{\text{in}}$ the charging energies are more closely spaced. Our calculations are in excellent agreement with recent spectroscopic results [10] for $\epsilon_{\text{out}} = 6$.

FIGURES

FIG. 1. Part (a) illustrates the process of loading three electrons into an otherwise neutral quantum dot. Part (b) shows the process of removing a single electron from a dot and placing it into another dot.

FIG. 2. The self-energy Σ_i^{pol} and the polarization energy $J_{i,j}^{\text{pol}}$ of an InAs quantum dot (diameter $D = 30.3 \text{ \AA}$) are shown as a function of the outside dielectric constant ϵ_{out} . The insets show the differences $\Sigma_p^{\text{pol}} - \Sigma_s^{\text{pol}}$ and $J_{s,p}^{\text{pol}} - J_{s,s}^{\text{pol}}$ as a function of ϵ_{out} . The vertical arrows indicate the value $\epsilon_{\text{out}} = \epsilon_{\text{in}}$.

FIG. 3. The central panel shows the dependence of a the electron charging energies $\mu_1 \cdots \mu_9$ and of the hole charging energies $\mu_{-1} \cdots \mu_{-6}$ on the external dielectric constant ϵ_{out} . The vertical arrow indicates the value $\epsilon_{out} = \epsilon_{in}$. The side panels show the calculated charging spectrum in the case $\epsilon_{out} = 1$ (left-hand panel) and $\epsilon_{out} = 20$ (right-hand panel). The zero of the energy scale corresponds to the highest energy valence state.
